

Capstone project sample

Introduction

Vitamin B12 is also referred to as cobalamin and it identifies a water-soluble vitamin utilized within the normal neurological function together with the development of the red blood cells. B12 is also identified as a cofactor within two metabolic pathways as it is utilized within the conversion of homocysteine together with methionine and within the conversion of methylmalonic acid (MMA) to succinyl-CoA (Alemras et al. 2007). The main sources of B12 include animal products such as meat, poultry, fish and milk; fortified foods including breakfast cereal together with B12 supplements. The recommended allowance does not incorporate a tolerable upper intake limit, as there is limited research on the toxicity capacity and limited data supporting the stipulation of an upper limit. Vitamin B12 is vital as it comprises an important element in DNA synthesis and individual neurological functioning. This necessitates continuous intake of the vitamin to enhance the prevention of possible hematologic and neuropsychiatric disorders upon lack of continued intake of the vitamin.

Through the analysis of the American and European intake of the vitamin, the intake levels identified meet the stipulated recommended daily allowance. However, keenness has to be observed regarding the absorption levels to ensure that individuals meet the required levels. This is particularly vital for vegetarians, as they do not consume animal products, which create the bulk of Vitamin B12 sources. In addition, individuals under any forms of medication, gastrointestinal patients, individuals over 50 years of age and anyone experiencing poor bouts of health remain at risk of having low levels of Vitamin B12 within their systems. Lack of vitamin B12 is influenced by poor adherence of the dietary stipulations leads to the identification of vitamin B12 deficiency among individuals.

Vitamin D is regarded a unique hormone as it may be produced within the skin through increased exposure to sunlight. Vitamin D is identified in two main forms: D2 and D3. Vitamin D2 is obtained through the UV irradiation of the yeast sterol ergosterol, which is naturally identified within sun-exposed mushrooms. Vitamin D3 synthesis process occurs within the skin and is identified within several oil-rich

fish including the salmon, mackerel and herring. It is also available in synthesized form from the cholesterol precursor 7-dehydrocholesterol, which is identified within the skin and may be obtained from lanolin. Vitamin D₂ and D₃ are utilized in the food fortification process and also within vitamin D supplements. The ingested vitamin D is integrated within chylomicrons that are consequently absorbed within the lymphatic system through the blood. Vitamin D ingested through the skin or diet remains biologically inert, which necessitates hydroxylation within the liver through the use of the vitamin D-25-hydroxylase to 25 (OH) D (3, 8). This necessitates further hydroxylation of 25 (OH) D within the kidneys through the use of 25 (OH)-1-OHase (CYP27B1) to develop a biologically active form of vitamin D 1, 25 (OH)₂ D. This enhances the interaction processes with vitamin D nuclear receptor in existence within the small intestine, kidneys together with other tissues within the body. 1, 25 (OH)₂ D influences the absorption of intestinal calcium. This identifies vitamin D as a vital element in the absorption of calcium and phosphorous as lack of the vitamin would identify 10 to 15% absorption of dietary calcium and 60% absorption of phosphorus. This identifies that vitamin D sufficiency influences calcium and phosphorous absorption by up to 30-40% and 80% respectively. Through increased interactions between 1, 25 (OH)₂ D and the vitamin B receptor within the osteoblast enhance the stimulation of the expression of receptor activator of nuclear factor κB ligand. This enhances the interaction with the receptor activator of nuclear factor κB aimed at inducing immature monocytes to develop into mature osteoclasts that influence the dissolution of the matrix leading to increased production of calcium together with other minerals from the skeleton. The above identifies that the vitamin D receptor remains present within the majority of the tissues and cells within the body thus providing 1, 25 (OH)₂ D with a myriad of biological functions including the inhibition of cellular proliferation and the inducing of terminal differentiation, the inhibition of rennin production and the stimulation of macrophage cathelicidin production. The above seeks to identify that vitamin D is vital within the body as it enhances the regulation of cell growth, bone formation, immune function, increased muscle strength, hair growth, fighting-off infections and the reduction of risk of autoimmune diseases.

Background and Significance of the Problem

Vitamin B12 deficiency can influence the identification of numerous hematologic and neuropsychiatric disorders, which may however be reversed upon the identification of early diagnosis and immediate treatment. However, the exact prevalence levels of vitamin B12 within the general population remain unknown. However, the incidence is identified as increasing with age. A study conducted by Packer et al. (2007) identified that 15% of adults who were older than 65 years projected high deficiencies of vitamin B12. Continued ubiquitous utilization of gastric acid –blocking agents influence the identified decreased levels of vitamin B12, which influence the increased levels of vitamin B12 deficiency realized. Through the analysis of the increasing use of the agents coupled with an increasing aging population among the developed nations, the actual prevalence of vitamin B12 may be identified higher in comparison to the provided statistics. The common symptoms of B12 deficiency include neuropathic (paresthesias, numbness and weakness), myelopathic (abnormal gait), cerebral (dementia, depression, memory loss) and in dire cases the deficiency is identified as hematologic whereby the patient suffers from severe anemia. In addition, vitamin B12 deficiency has been linked to indirect cardiovascular effects. Vitamin B12 deficiency may enhance the production of hyperhomocysteinemia, which identifies a risk factor for atherosclerotic disease. Folic acid supplementation is provided to influence the reduction of homocysteine levels as an avenue utilized in the prevention of coronary artery disease. However, there has been limited emphasis upon the role of vitamin B12 deficiency in the development of cardiovascular disease. This possibility is increasingly vital in the consideration of vitamin replacement therapy as folic acid supplementation may hide a growing vitamin B12 deficiency, which will influence the progression of the experienced neurologic disease. This necessitates the determination of vitamin B12 deficiency prior to the initiation of folic acid therapy.

In the human body system, two enzyme reactions remain dependent upon vitamin B12. The first reaction involves the conversion of methylmalonic acid into succinyl-CoA through the utilization of B12 as a cofactor. This identifies that vitamin B12 deficiency may influence the identification of increased levels of serum methylmalonic acid. The second reaction involves the conversion of

homocysteine to methionine through the utilization of vitamin B12 together with folic acid as the cofactors. In this reaction, the identification of a deficiency in vitamin B12 or folic acid may influence the identification of increased levels of homocysteine. This necessitates the development of an intricate understanding of vitamin B12's absorption cycle to provide a better analysis of the potential causes of deficiency. The existence of the acidic environment within the stomach influences the breakdown of B12 identified within food. Through the release of the intrinsic factor by the parietal cells within the stomach, vitamin B12 remains bound to the duodenum. The intrinsic factor influences the absorption of vitamin B12 within the terminal ileum. There also exists an alternate system of vitamin B12 absorption that does not require the intrinsic factor as influences the binding of vitamin B12 upon absorption to transcobalamin II, which is consequently transported throughout the body. Therefore, interruption of either steps places an individual at high risk of developing deficiency.

Vitamin D deficiency is characterized by the identification of inadequate provision of minerals to the skeleton. In children vitamin D deficiency influences the development of rickets, which involves the widening at the end of the long bones, rachitic rosary together with other deformations within the skeleton including outward and inward deformities of the lower limbs leading to the identification of bowed legs and knocked-knees. Among adults, vitamin D deficiency leads to the identification of a mineralization defect within the skeleton leading to the development of osteomalacia. In addition, vitamin D deficiency among adults initiates the mobilization of calcium from the skeleton leading to the development of porotic bone. The identification of a change within the production of vitamin D₃ may influence the identification of a vitamin D deficient state. Additionally, the identification of any alterations within the 1, 25 (OH)₂ D within its receptor may influence the identification of vitamin D₃ deficiency, which is characterized by metabolic bone disease together with the manifestation of a myriad of biochemical abnormalities. As previously identified vitamin D deficiency influences the identification of a decrease in the levels of ionized calcium within the blood, which influences the identification of an increase in the production and secretion capacity of PTH. PTH influences the mobilization of calcium the skeleton, which enhances the conservation of renal loss of calcium leading to the identification of

an increase in the renal excretion of phosphorous. This leads to the identification of normal fasting serum calcium with low-normal serum phosphorous.

Statement of the Problem

Increased deficiency levels of vitamin B12 and vitamin D3 levels within the body necessitate the integration of further research and analysis regarding the importance of conducting regular check up on the existent levels among individuals.

Statement of the Purpose

This study seeks to provide a conclusive analysis regarding the importance of checking the levels of vitamin B12 and vitamin D3 levels within the body. This will be enhanced through the integration of a conclusive analysis of the deficiency levels identified through the analysis of the healthy and unhealthy levels required within the body. This study will incorporate an analysis from previous research conducted by several authors within the field, who have provided an analysis of the diagnosis, causes of deficiency and the most preferred follow-up procedure that may be incorporated.

The study will incorporate a literature review section, which will provide an analysis of the importance of checking vitamin B12 and vitamin D3 as conducted from other researchers within the field. This is vital for the study as it will enhance the provision of wide array of data that will provide conclusive analysis from the past, present and future efforts that may be integrated to limit the levels of deficiency experienced. The study will also incorporate a methodology section, which will outline the data collection methods to be utilized within the study, which provide great relevance and enhance the achievement of the study objectives. This will be followed through the integration of the findings and discussion section, which will provide an analysis of the study and enhance the development of the study recommendations and conclusion.

Review of Literature

The diagnosis of B12 has overtime developed its basis upon the analysis of low serum vitamin B12 levels, which are identified at less than 200pg per mL together with the analysis of the available clinical evidence pertaining to the disease.

However, the majority of studies identify that older patients present more of neuropsychiatric disease in the absence of hematologic findings. In addition, the provision of measurements of metabolites including methylmalonic acid and homocysteine are identified more sensitive to the diagnosis of vitamin B12 deficiency in comparison to the individual measurement of serum B12 levels. A recent study conducted on 406 patients with vitamin B12 deficiency indicated that 98.4% had elevated serum methylmalonic acid levels with 95.9% identified as having elevated serum homocysteine levels. Only one patient from the 406 had indicated normal levels of both metabolites, which raised the sensitivity level to 99.8% at the period when the methylmalonic acid and homocysteine levels are utilized during the diagnosis. Twenty-eight percent of the patients within the study exhibited normal hematocrit levels with 17% identifying normal mean corpuscular volumes. In a study conducted by Lin et al. (2011) regarding patients with known pernicious anemia who had not been provided with the necessary maintenance levels of vitamin B12 injections for a period spanning several months to years, they exhibited an increase in methylmalonic acid together with decreased levels of hematocrit. The findings from the study identify that methylmalonic acid and homocysteine levels may be utilized as early markers for tissue vitamin B12 prior to the identification of hematologic indications.

Continued utilization of methylmalonic acid and homocysteine levels within the diagnosis of vitamin B12 deficiency has enhanced the provision of varied results. In the event that increased homocysteine or methylmalonic acid levels or through the normalization of the metabolites in response to replacement therapy, they are utilized as diagnostic criteria for vitamin B12 deficiency. The majority of the patients subjected to the process accounting for 50% have identified high levels of serum vitamin B12. This espouses that the utilization of a low serum vitamin B12 level as the main diagnosis may eliminate half of the patients with actual tissue B12 deficiency.

Causes of Vitamin B12 Deficiency

Factors influencing the identification of vitamin B12 deficiency are incorporated into three main categories: nutritional deficiency, malabsorption syndromes together with other gastrointestinal causes.

Nutritional Deficiencies

The main dietary sources for vitamin B12 include meat and dairy products. In a typical diet an individual derives 5 to 15 mcg of vitamin B12 on a daily basis, which is identified higher than the recommended daily dosage stipulated at 2 mcg. This identifies that the majority of individuals maintain a high vitamin B12 reserve, which has the capability of lasting two to five years. However, nutritional deficiency may be identified within certain populations. For instance elderly patients who regularly take up tea and toast diets and consume high levels of alcohol are identified as having a higher risk for vitamin B12 deficiency. In addition, the dietary stipulations followed by strict vegetarians place them at high risk of experiencing the stipulated deficiency levels.

Malabsorption Syndromes

The main disorder identified within this category is the pernicious anemia, which refers to an autoimmune disease that affects the gastric parietal cells. Therefore, any form of destruction identified among these cells limits effective production of intrinsic factor, which limits the absorption levels identified regarding vitamin B12. Laboratory evidence incorporated regarding parietal cell antibodies is identified at 85% to 90% sensitive regarding the diagnosis of pernicious anemia. However, the majority of tests identify that the presence of parietal cell antibodies remains nonspecific and occurring within other autoimmune states. The intrinsic factor antibody is identified as being 50% sensitive, but is identified as being highly specific for the diagnosis of pernicious anemia. In addition, a Schilling test may be utilized in the development of a distinction among intrinsic factor-related malabsorption in the diagnosis process of pernicious anemia. Schilling test results have been used overtime to enhance the determination process regarding whether the patient requires parenteral or oral vitamin B12 supplementation. However, the development of this distinction is rendered unnecessary as the majority of the recent evidence espouses towards the utilization of a B12 absorption pathway that remains independent of intrinsic factors. In addition, several studies have identified that oral replacement is identified equal in efficacy to intramuscular therapy. However, several studies espouse that successful treatment may also be realized through the utilization of oral replacement therapy. This has enhanced the development of several

questions regarding the utility of the Schilling test as it is regarded complicated to perform. This has rendered the identification of vitamin B12 difficult together with increased complexities within the results interpretation process for patients suffering from renal insufficiency. The process of food-bound malabsorption is identified when vitamin B12 bound to protein within food is incapable of being cleaved and released. This is influenced by the integration of any process that provides some level of interference with gastric acid production that may lead to the identification of certain levels of impairment. Atrophic gastritis together with hypochlorhdria is regarded a major cause among the elderly. In addition, subtotal gastrectomy may influence the identification of vitamin B12 deficiency.

Widespread and prolonged use of histamine H2-receptor blockers together with proton pump inhibitors for ulcer disease influence irregular breakdown of vitamin B12 from food leading to increased malabsorption and consequent depletion of B12 levels within the body.

Recent studies espouse that long-term utilization of omeprazole may influence the identification of decreased levels of serum vitamin B12 levels. However, more studies require to be incorporated to enhance the identification of the incidence and prevalence of vitamin B12 deficiency through increased screening for subclinical BB12 deficiency should be enhanced among patients who have experienced long-term acid-suppression therapy.

Other Causes

Patients who have exhibited vitamin B12 deficiency together with chronic gastrointestinal symptoms including dyspepsia, recurrent peptic ulcers or diarrhoea necessitate the integration of an evaluation process regarding several factions including Whipple's disease, which refers to a bacterial infection that limits the absorption levels identified within the body. In addition, the patient may be tested for Zollinger-Ellison syndrome, which influences the development of peptic ulcers and diarrhea. In addition, patients who have had a history of intestinal surgery, strictures or blind lops may identify high levels of bacterial overgrowth, which may limit the provision of the necessary amounts of vitamin B12 within the small bowel together with increased manifestation of tapeworms and other intestinal parasites. In addition, congenital transport-protein deficiency may

influence the lack of vitamin B12 leading to the identification of increased deficiency levels.

Vitamin D deficiency

Vitamin D deficiency among adults is described as being endemic. There has been an increasing number in children and adolescents who are identified as being vitamin D deficient. Historically, vitamin D deficiency has been defined as a 25 (OH)D of less than 20 ng/ml. Therefore, vitamin D insufficiency is defined as 25(OH) of 21-29 ng/ml. Through the analysis of the provided definitions, several estimates identify that 20-100% of the American and European elderly men and women within the community exhibit high vitamin D deficiency levels. Vitamin deficiency is identified common in Australia, the Middle East, India, Africa and South America. The deficiency levels are also identified high in the United States as 50% of the Hispanic and African-American adolescents together with 8% of white preadolescent girls exhibited 25 (OH)D below 20 ng/ml. Additionally, 42% of African-American girls and women within the ages of 15 and 49 years identified a blood level of 25 (OH) D below 15 ng/ml. Pregnant and lactating women consuming prenatal vitamins together with calcium supplements with vitamin D are identified as being at high risk for vitamin D deficiency.

Causes of Vitamin D Deficiency

The main source of vitamin D for children and adults remains as increased exposure to sunlight. This is vital as limited foods contain vitamin D. This identifies the main cause for vitamin D deficiency as limited exposure to sunlight. In addition, wearing sunscreen with sun protection limits the level of vitamin D synthesis on the skin by up to 95%. This identifies that individuals with a darker skin tone are provided with natural sun protection hence, require three to five times longer identifying the same levels of vitamin D as individuals with white skin tone.

There exists an inverse correlation between serum 25 (OH) D and the body mass index (BMI) greater than 20k/m², which identifies that obese individuals experience vitamin D deficiency. Patients identifying one of the fat malabsorption syndromes together with bariatric patients are identified as challenged in the absorption of fat-soluble vitamin D together with patients with nephrotic

syndrome lose 25 (OH) D and remain bound to vitamin D-binding protein within the urine. In addition, patients administering a wide range of medication including anticonvulsants together with antiviral drugs are identified at higher risk as the drugs influence the catabolism of 25 (OH)D and 1,25 (OH)₂D. Patients with chronic granuloma-forming disorders including some lymphomas and primary hyperparathyroidism identify high levels of metabolism at 25 (OH) D to 1, 25 (OH) ₂ D are identified at high risk of vitamin D deficiency.

What you should expect from a capstone project example

Once you have acquired a **capstone project example**, you should certainly use it as your guide and not your source of information. The example is supposed to act as a blueprint and so you should use in that way. Now there are those who just duplicate the content in the project example and expect to be awarded good grades for their projects. That cannot happen especially so if the professor responsible for marking your projects knows your writing standards, he will certainly recognize that the project you submitted is not actually yours. You should therefore learn how to plan your content in the project by using the example and not use it the data in the example.

The advantages of a capstone paper sample

You will agree with me that you might not have the adequate time to write and submit a [capstone projects](#) within the set deadline. Due to the limited amount of time, you might not have the time to research on such things like how to write such a project as well as research on what content is appropriate for that project. It is during situations like this that you may choose to use a sample project to guide you through the writing process. This will actually save a lot of time which you may use to do something else. The sample project will also eliminate the chances of you making mistakes since you will follow the layout in the **capstone paper sample**.

Important points about using the sample projects

To ensure that your project is unique and original, you should never copy the content in the sample paper. Stick to the tips highlighted above here and you will certainly be in a position to submit a project that is of high quality by simply using the available project samples.
